

Sales Optimization by Allowing Controlled Negative Profit Scenarios

Executive Summary

In high-velocity lead marketplaces, rigid “positive profit per transaction” constraints often leave value on the table. A more mature optimization framework allows *controlled negative margins on individual transactions* when they unlock higher aggregate profitability, better inventory utilization, or downstream monetization. This article outlines a quantitative approach to sales optimization that explicitly incorporates probabilistic sale outcomes, dynamic pricing, and volume-profit trade-offs.

1. Problem Framing and Key Variables

We model the lead sale process as a stochastic optimization problem, where pricing decisions directly impact the probability of sale and, ultimately, total expected profit.

Let:

- **P_min** — Minimum acceptable price set by the advertiser
- **P_lender** — Price a lender is willing to pay for a lead
- **P_advertiser** — Payout to the advertiser upon sale
- **Profit per lead** = $P_{\text{lender}} - P_{\text{advertiser}}$
- **p_s(P_lender)** — Probability that a lead sells at price P_{lender}
- **N** — Total number of leads
- **E** — Expected total profit over N leads

The key insight is that *profit is probabilistic, not deterministic*. A lower margin with a higher sale probability can outperform a higher margin with poor conversion.

2. Objective Function

The core objective is to maximize expected profit:

$$E = \sum_{i=1}^N (P_{\text{lender},i} - P_{\text{advertiser},i}) \cdot p_s(P_{\text{lender},i})$$

Constraints

- $P_{\text{lender},i} \geq P_{\text{advertiser},i}$
- $P_{\text{advertiser},i} \geq P_{\text{min},i}$
- $p_s \in [0,1]$

This formulation already enables rational acceptance of low-margin or even negative-margin scenarios if they improve total expected value.

3. Modeling Sale Probability

Sale probability is modeled as a decreasing function of lender price:

$$p_s(P_{\text{lender}}) = e^{-k(P_{\text{lender}} - P_{\text{min}})}$$

Where:

- $k > 0$ controls price sensitivity

This captures real-world behavior: as price increases, deal velocity drops non-linearly.

4. Optimization Strategies

Case 1: Static Pricing Optimization

With fixed advertiser and lender price thresholds:

$$E = N \cdot (P_{\text{lender}} - P_{\text{advertiser}}) \cdot p_s(P_{\text{lender}})$$

To find the optimal lender price:

$$\frac{\partial E}{\partial P_{\text{lender}}} = N \cdot [p'_s(P_{\text{lender}})(P_{\text{lender}} - P_{\text{advertiser}}) + p_s(P_{\text{lender}})]$$

Setting the derivative to zero yields the revenue-maximizing price point. In practice, this provides a defensible pricing benchmark rather than a hard rule.

Case 2: Dynamic Pricing with Negative Profit Tolerance

In a dynamic system, advertiser payouts can be adjusted iteratively:

1. Compute expected profit at current $P_{\text{advertiser}}$
2. If $E \geq 0$, accept pricing
3. If $E < 0$, decrement $P_{\text{advertiser}}$ by ΔP
4. Recompute until E becomes non-negative

This approach enables *temporary negative unit economics* while protecting portfolio-level profitability.

5. Volume vs. Profit Trade-Off

In growth or liquidity-constrained phases, the objective may shift from pure profit maximization to volume maximization under a profitability constraint.

Objective:

$$V = \sum_{i=1}^N p_s(P_{\text{lender},i})$$

Constraint:

$$\sum_{i=1}^N (P_{\text{lender},i} - P_{\text{advertiser},i}) \cdot p_s(P_{\text{lender},i}) \geq 0$$

This becomes a linear programming problem:

- **Maximize:** Total sold volume
- **Subject to:** Non-negative total profit

This framework is especially effective when scale, lender retention, or data acquisition have strategic value beyond immediate margin.

6. Numerical Illustration

Assume:

- $P_{\text{min}} = 100$
- $P_{\text{lender}} = 120$
- $P_{\text{advertiser}} = 100$
- $k = 0.05$

Step 1: Sale Probability

$$p_s(120) = e^{-0.05(120-100)} = e^{-1} \approx 0.3679$$

Step 2: Expected Profit

For $N = 100$:

$$E = 100 \cdot (120 - 100) \cdot 0.3679 \approx 735.8$$

Despite a moderate sale probability, the pricing structure yields strong expected profitability.

Step 3: Dynamic Adjustment

If E becomes negative at lower lender prices, advertiser payouts are adjusted downward until portfolio-level profitability is restored.

Strategic Takeaways

- Per-lead profitability is a misleading KPI; expected value is the correct optimization target
- Allowing controlled negative margins can materially increase total profit
- Probability-aware pricing outperforms static margin rules
- Linear and non-linear optimization models are practical tools, not academic exercises

In short, sales optimization is not about avoiding losses—it's about *allocating them intelligently* to maximize long-term enterprise value.
